### Summary

That molecular markers allow fast recovery of recurrent parent genotype in backcross programs is undisputed. Restriction Fragment Length Polymorphisms (RFLP's) were used in maize to introgress by backcross a transgene construct, containing phosphinothricin resistance and insecticidal protein genes, from a transformed parent into an elite inbred line. At each generation plants carrying the transgene construct were selected based on their phosphinothricin resistance, and further characterized with RFLP's. Both maximum recovery of recurrent parent genotype and minimum linkage drag were taken into account for marker-based selection. Embryo rescue was used to shorten generation time. Progress towards recurrent parent genotype was spectacular. Levels of recurrent parent genotype recovery which would normally be observed, in the absence of selection, in the BC<sub>2</sub> generation were obtained at the BC<sub>3</sub> generation, about one year after BC<sub>1</sub> seeds had been planted. Besides the evidence already provided by RFLP's, phenotypic evaluation of the backcross-derived near-isogenic lines will constitute an additional check of the completeness of the conversion.

### Introduction

Backcrossing has been a common breeding practice for as long as elite germplasm has been available. It has mainly been used to introgress single Mendelian traits, such as disease resistances or quality factors, into elite germplasm (Allard 1960; Hallauer and Miranda 1981). One of the most attractive attributes of backcrossing is that it allows to perform targeted modifications without disrupting the existing overall genetic balance of the recurrent parent.

However, production of fully converted near isogenic lines through classical backcrossing procedures is a lengthy procedure, if at all possible. Theoretically, a minimum

BEST AVAILABLE COPY

of seven classical backcross generations are required to recover more than 99% of recurrent parent genotype, assuming no linkage drag. The attractiveness of classical backcross procedures is therefore substantially diminished for crops, such as maize (*Zea mays* L.), where the turn-over of elite cultivars is very fast. In addition, full recovery of recurrent parent genotype is usually not achieved through classical backcrossing, which may result in deleterious agronomic effects. Murray *et al.* (1988) reported about 90% recurrent parent genotype recovery in two BC<sub>10</sub>-equivalent conversions (A632Ht and A632Rp) of the maize line A632. The conversions had retained respectively 4 and 7 donor fragments in addition to the one carrying the gene of interest.

Reduction in the number of backcross generations needed to obtain fully converted individuals has been shown theoretically, or from simulations, to be achievable through the use of molecular markers (Tankaley *et al.* 1989; Hospital *et al.* 1992; Jarboe *et al.* 1994). Because they provide thorough characterization of the genetic variability at each backcross generation, markers allow to take full advantage of this variability by applying the highest possible selection intensity.

Efficiency of marker-assisted backcrossing was investigated through an experiment aimed at introgressing a single genetic factor (a transgene construct) from a donor into a recipient maize line.

## Materials and methods

### Plant Material

A hemizygous transgenic maize line of Lancaster origin was used as donor parent to introgress its transgene construct, through repeated backcrossing, into a recipient parent from the Stiff Stalk germplasm group. Both parents are proprietary elite lines. The transgene construct carries both a phosphinothricin resistance gene and synthetic genes encoding the entomotoxic fragment of the CryIA(b) *Bacillus thuringiensis* protein (Koziet *et al.* 1993). Transformation was achieved through microprojectile bombardment (Koziet *et al.* 1993) and resulted in a single insertion (*Bt* locus), on chromosome 1 (Figure 1).

### Backcross protocol

The F<sub>1</sub> progeny of the cross between the donor and the recipient was screened for the presence of the transgene construct by applying Basta, a phosphinothricin-based herbicide, onto each plant. Resistant individuals were then used to generate BC<sub>1</sub> progeny.

For each backcross generation, except the BC<sub>4</sub>, individuals were planted in multipots and sprayed with Basta to eliminate those which did not carry the transgene construct. To avoid the stress resulting from treatment with Basta, BC<sub>4</sub> plants carrying the transgene construct were identified using Southern blots probed with the *pat* and *Bt* genes. Resistant plants were transplanted in an open-soil greenhouse and leaf-sampled for molecular marker

analyses. Results of marker analysis were used for selection. A single plant was rescued and transferred onto tissue culture medium, before being regenerated. On average, four months.

### Molecular marker analysis

Restriction Fragment Length Polymorphism (RFLP) analysis was performed on DNA extracted from plants in all four generations. Markers were chosen from among those that provided coverage of the entire genome, contained two loci tightly linked to the transgene (within 10 recombination units away) (Figure 1) and were tightly linked to the transgene. In the BC<sub>4</sub> generation, the selected BC<sub>4</sub> plant was heterozygous for the transgene and the reference population was homozygous for the transgene.

### Selection procedure

At each generation plants were screened for the presence of the transgene and the recurrent-parent genotype and an attempt to integrate both criteria was made. Missing values were not included in the selection procedure. The best ranking one of those for which the BC<sub>3</sub> selection was available was selected.

## Results and discussion

### Selection for the gene of interest

The observed segregation ratio was significantly different ( $P < 0.05$ ).

### Recurrent parent genotype

analyses. Results of marker analyses were made available at the latest two weeks after  
 flowering. A single plant was selected, of which all backcross-derived embryos were  
 reached and transferred onto tissue culture medium. Plantlets that developed from these  
 embryos first underwent a greenhouse acclimation phase, while still growing on tissue  
 culture medium, before being transplanted into multipots. Backcross cycles lasted, on  
 average, four months.

#### Molecular marker analyses

Restriction Fragment Length Polymorphisms (RFLP's) were used to establish  
 genotypes in all four generations. RFLP detection involved either radioactive or  
 chemiluminescent techniques. For the BC<sub>1</sub> generation, 61 marker-enzyme combinations  
 were chosen from among those revealing polymorphism between donor and recipient. They  
 provided coverage of the entire genome, defining intervals of about 25 cM in size, and  
 contained two loci tightly linked to the *Bt* locus, CG320 and CG415, respectively 5 and 16  
 recombination units away (Figure 1). For subsequent generations, markers analyzed in the  
 BC<sub>n+1</sub> generation comprised both those for which the selected BC<sub>n</sub> plant was heterozygous,  
 or tightly linked ones, and additional ones located in chromosomal segments for which the  
 selected BC<sub>n</sub> plant was heterozygous (Table 1). Marker map positions were obtained from  
 independent reference populations and confirmed by analysis of segregation in the BC<sub>1</sub>  
 generation.

#### Selection procedure

At each generation plants were ranked based both on the percentage of homozygous  
 recurrent-parent-genotype and on the extent of linkage drag around the *Bt* locus, in an  
 attempt to integrate both criteria. Plants for which two or more adjacent markers had  
 missing values were not included in the analyses. Success or failure of the pollinations also  
 contributed to the selection procedure. One single plant was selected at each generation: the  
 best ranking one of those for which a backcross progeny of size 100 or more (50 or more  
 for the BC<sub>3</sub> selection) was available.

### Results and discussion

#### Selection for the gene of interest

The observed segregation ratios for phosphinothricin resistance (Table 1) were not  
 significantly different ( $P < 0.05$ ) from the expected 1:1, as shown by Chi-square tests.

#### Recurrent parent genotype recovery

Statistics for the genotyped plants are summarized in Table 1. Calculations were  
 performed taking the whole genome into account, including the *Bt* locus. The "perfect"  
 backcross-derived plant therefore counts one heterozygous chromosome segment, that

\*\*\* Including the segment carrying the transgene construct.

comprising the *Bt* locus. It also displays 99.36% of homozygous recurrent-parent-genotype. The remaining 0.64% corresponds to the average relative length of the chromosome segment containing the *Bt* locus, which depends on the two flanking markers chosen.

The mean percentage of homozygous recurrent-parent-genotype of the BC<sub>1</sub> generation was slightly lower than the expected 50%. This can be explained by linkage drag around the *Bt* locus, given that this percentage was computed based only on plants selected for heterozygosity at the *Bt* locus. For all other backcross generations the mean percentage of homozygous recurrent-parent-genotype was much higher than what would have been observed, should no selection have been done (Figure 2).

The percentage of homozygous recurrent-parent-genotype of the selected plant (Table 1) and the average of the five largest values (Table 1) were always very similar to one another, and much superior to the population mean value (Figure 2). The percentage of homozygous recurrent-parent-genotype of the selected plant was found only once, in the BC<sub>2</sub> generation, to be smaller than the average of the five largest values. This corresponded to the only time when the selected plant was not the one with the maximum percentage of homozygous recurrent-parent-genotype. The plant had been selected because it displayed a favorable recombination on one side of the *Bt* locus (Figure 1).

The percentage of homozygous recurrent-parent-genotype of the selected BC<sub>1</sub> plant was almost equal to that of an unselected BC<sub>2</sub>, that of the selected BC<sub>2</sub> was larger than that of an unselected BC<sub>3</sub>, that of the selected BC<sub>3</sub> was barely smaller than that of an unselected BC<sub>6</sub>, and that of the selected BC<sub>4</sub> was equal to that of the "perfect" backcross-derived plant, given the set of markers that was used. Such rates of recurrent parent genotype recovery are consistent with results of simulation analyses. Jarboe *et al.* (1994) who used the maize genome as a model reported that three backcross generations and 80 markers were needed to recover 99% of recurrent parent genotype.

#### Number of donor chromosome segments

The number of heterozygous chromosomal segments decreased from one backcross generation to the next. Plants selected at each generation were not necessarily those which had the lowest number of heterozygous chromosomal segments (Table 1). However, with the set of markers used, BC<sub>3</sub> and BC<sub>4</sub> plants were recovered which contained only one heterozygous chromosomal segment: that comprising the *Bt* locus.

#### Linkage drag

Linkage drag around the *Bt* locus was estimated, relative to the length of chromosome 1. Its value was found to lie between 24.0 and 48.4% for the selected BC<sub>1</sub> individual, between 17.6 and 34.8% for the selected BC<sub>2</sub>, between 2.0 and 24.0% for the selected BC<sub>3</sub>, and between 0.0 and 8.4% (respectively 0.0 and 14.5 cM) for the selected BC<sub>4</sub>.

The two values given for each generation correspond to extreme positions of flanking the transgene construct loci. BC<sub>4</sub> is likely to be less than 1.3% appear to be somewhat high, reflect drag, it is much lower than what Stam and Zeven 1981; Tanksley *et al.* of tomato cultivars obtained by a 12 Tanksley (1989) found that the sizes cM.

#### Conclusion

These results clearly demonstrate quality advantages over classical breeding through backcrossing. Only four backcrosses in less than a year and a half from plant genotypically fully converted. New genotype could proceed even faster appropriate protocol and resources allocated.

Comparison of BC<sub>4</sub>-derived 1 markers and agronomic performance order to confirm the completeness of

- MURRAY, M.G., Y. MA, J. ROMERO: fragment length polymorphism: what

homozygous recurrent-parent-genotype. The relative length of the chromosome between the two flanking markers chosen.

A parent-genotype of the BC<sub>1</sub> generation was explained by linkage drag around the *Bt* locus based only on plants selected for BC<sub>1</sub> generations the mean percentage of *Bt* was higher than what would have been expected (Table 2).

A parent-genotype of the selected plant (Table 1) were always very similar to an unselected plant (Figure 2). The percentage of *Bt* was found only once, in the five largest values. This corresponded to one with the maximum percentage of *Bt* had been selected because it displayed a *Bt* genotype (Figure 1).

A parent-genotype of the selected BC<sub>1</sub> plant of the selected BC<sub>2</sub> was larger than that of an unselected plant. The percentage of *Bt* was smaller than that of an unselected plant of the "perfect" backcross-derived plant. The rates of recurrent parent genotype were analyzed. Jarboe *et al.* (1994) who used backcross generations and 80 markers to identify *Bt* type.

Percentages decreased from one backcross generation were not necessarily those which were expected (Table 1). However, with backcross generations which contained only one *Bt* locus,

percentages relative to the length of chromosome were 4% for the selected BC<sub>1</sub> individual, between 2.0 and 24.0% for the selected BC<sub>2</sub> (14.5 cM) for the selected BC<sub>4</sub>.

The two values given for each generation are extreme values of linkage drag, which correspond to extreme positions of the crossing-overs in the marker-defined intervals flanking the transgene construct locus. Therefore the true linkage drag value of the selected BC<sub>4</sub> is likely to be less than 1.3% of the genome. Although this maximum value may appear to be somewhat high, reflecting the limited selection pressure put here on linkage drag, it is much lower than what would be expected from classical backcross programs (Stam and Zeven 1981; Tanksley *et al.* 1989). Practically, in a study of *Tm-2* conversions of tomato cultivars obtained by a large number of classical backcross cycles, Young and Tanksley (1989) found that the sizes of the introgressed fragments ranged between 4 and 51 cM.

### Conclusion

These results clearly demonstrate that molecular markers provide important time and quality advantages over classical procedures for the production of near-isogenic lines through backcrossing. Only four backcross generations were necessary to recover, in less than a year and a half from planting of the BC<sub>1</sub>'s, individuals which appeared to be genotypically fully converted. Nevertheless, it is likely that recovery of recurrent parent genotype could proceed even faster than in the experiment described herein, should the appropriate protocol and resources (population size, number and position of markers) be allocated.

Comparison of BC<sub>4</sub>-derived lines with the recurrent parent for both morphological markers and agronomic performance (including hybrid performance) will be performed in order to confirm the completeness of the conversion.
